Abstract

Purpose The purpose of the study is to evaluate the effect of different animal product wastes and plant compost on survival and growth of earthworm (*Eisenia fetida*).

Methods The study is realized in a vermibin for a duration of 90 days. The initial physico-chemical parameters (pH, humidity, ash, organic matter, carbon, nitrogen, phosphorus and C:N ratio) were determined in each waste of the different substrates before the study. Six waste products (pig, poultry, rabbit, cattle, sheep and vegetal compost) in triplicate (6 × 3) were used for earthworm production. In each 12-l content vermibin, 2 kg of substrate and 30 g of mature earthworms were sown. Each month, the growth control was realized by earthworms harvest and weighing. The earthworms were put back in substrate in vermibin and 500 g of substrate were completed. The pH was measured every week.

Results The physico-chemical parameters (pH, ash, organic matter, carbon, phosphorus, nitrogen and C:N ratio) varied ($P < 0.05$) according to different substrate. The C:N ratio of different organic substrates are in the range of 8.46 in vegetable compost to 19.39 in pig dung. At the end of study the biomass gain and mortality varied

($P < 0.05$) according to different treatments. The growth rate varied according to different organic waste ($P < 0.05$) and ranged between -0.06 ± 0.02 (vegetable compost) and 1.34 ± 0.11 (cow dung). Maximum weight gain and highest growth rate were attained with cow dung. Earthworm biomass gain in different animal wastes is in the order of: cow > pig > rabbit > poultry > sheep > compost vegetable.

Conclusion The animal wastes (cow, sheep, pig, rabbit and poultry) and vegetable compost can be used to produce the earthworm. But the growth and produce depend on the biochemical quality of the substrates and the availability and facility for using a nutritive element.

Keywords *Eisenia fetida* · Growth · Animal waste · Vegetable compost · Production · Vermicompost

Introduction

According to growing trend of using chemical fertilizers in agriculture and its associated environmental impacts specially in developing countries, application of management strategies are necessary to reduce its effects. Nonfundamental and long-term consumption of fertilizers not only lead to degradation of soil quality, but also can reduce product quality, that disrupt the natural balance of the ecosystems and increases the environmental pollution. In the past half century, using chemical fertilizers significantly has increased yield of the agriculture products. The environmental stability results from the use of fertilizers, on one hand and on the other hand, will face problems food production in the coming decade (Tohidinejad et al. 2011). The vermiculture as means of reducing the greenhouse gas emissions that have negative impacts on the environment,

although waste sector produces the least quantity of greenhouse gases (Roghaye 2012).

The management of organic waste, in the circumstance the animals dung in the farms represented a serious problem in Benin. However, a good management of this organic waste can contribute a supply an animal protein for aquaculture and organic fertilizer for market garden produce. Vermicomposting technology is neither developed and nor practiced in Benin; whereas, this technology constitutes one of the tools for management an organic waste (Manyuchi and Nyamunokora 2014; Manyuchi et al. 2014; Manyuchi and Phiri 2013). It has been described as a biological process for converting solid waste into a stable, humus-like product, which is used as a soil conditioner (Talashikar 1989). The vermicompost has many advantages: obtaining the earthworms biomass which one can valorize through the feed of the animals, especially in aquaculture (Roghaye 2012) and is biological manure very much used in vegetable production, for example into product the tomato and peppermint (Zucco et al. 2015; Ayyobi et al. 2014). The earthworms are used through the waste recycling organics urban, industrial and agricultural (Reinecke et al. 1992). Indeed, 1 kg of adults earthworm can convert up to 5 kg of waste per day and approximately 10 kg of adults can convert one ton waste per month (Mahmoud 2011). Many species could be used for these utilities. *Eisenia fetida* is the species who support the tropical climatic conditions. This species can reproduce normally at a temperature ranging between (20 and 25 °C) and can tolerate a temperature upto 29 °C (Tomlin 1981; Lee 1985; Curry 1998). It is an epigeic earthworm living on the upper surface of soils feeding mainly on plant litter and other organic debris available on the soil surface. As these earthworms can consume a variety of organic matter, they are most suitable for converting organic wastes into useful organic manures (Chattopadhyay 2012). This species can be used for composting *Azolla pinnata* (Ishtiyak and Anisa 2010), paper mill (Karn and Chakrabarti 2015) and for composting municipal solid wastes (Mishra et al. 2014). In Benin farms, the animals bred are often pig, poultry, rabbit, cattle, and sheep. The management of these wastes constitutes a problem in the farms. However, these wastes could be of value for vermicomposting. But the diet of these animals differs, which induced a difference of chemical quality of their waste. The aim of this study is to promote in Benin the vermicomposting in the farms with various animal wastes and to evaluate the impact of these various animal wastes (pig, poultry, rabbit, cattle, and sheep) on the earthworm biomass production. Moreover, the impact of the vegetable compost on the production of these earthworms will be also evaluated.

Materials and methods

Collection of earthworms

Adults of *E. fetida* (clitellum accented) were collected from lots of garbage in Benin National Agricultural Research Institute (INRAB) and grown in laboratory of research in the wetlands (LRZH) of Abomey-Calavi University.

Collection and preparation of organic substrates

Fresh waste of different animals (pig, poultry, rabbit, cattle, and sheep) was collected from animal farms in Abomey-Calavi. The animal dung was used 14 days after the collection, because pre-composting is very essential to avoid the death of the worm (Gunadi and Edwards 2003). The plant compost obtained of the Abomey-Calavi University was used for our experimentation.

pH was determined using pH paper introduced in the wet substrate. Total carbon was measured using the method of Nelson and Sommers (1982). Organic matter was determined by $MO\% = C\% \times 1.724$. Nitrogen was determined according to Bremner and Mulvaney (1982). Total phosphorus was analyzed using the colorimetric method with molybdenum in sulphuric acid.

Culture of earthworms and growth studies

Six waste products (pig, poultry, rabbit, cattle, sheep and vegetal compost) in triplicate (6 × 3) were used for earthworm production. In each 12-l content vermibin, 2 kg of substrate and 30 g of mature earthworms were sown. Each month, the growth control was realized by earthworms harvest and weighing. The earthworms were put back in substrate in vermibin and 500 g of substrate were completed. The pH has been measured every week.

Zootechnical parameters and statistical analysis

Zootechnical parameters

$$GR = \frac{W_f - W_i}{t_2 - t_1} P = \frac{W_f - W_i}{Q}$$

with: W_i initial weight of the worms, W_f final weight of the worms, t_1 start of the experiment (in days), t_2 end of the experiment (in days), Q total waste (in kg), N_i initial number, N_f final number, P produce (g/earthworm/kg of waste), GR growth rate (mg/worm/day), WMI initial weight mean, WMF final weight mean

Statistical analysis

Treatment effect was evaluated using one-way analysis of variance (ANOVA) with StatView software after verifying the homogeneity of variance using “Hartley’s test” for each experiment. Significant differences between treatments means ($P < 0.05$) were determined using a Fisher’s least-significant difference test (Saville 1990). Results are given as mean \pm SE.

Results

Physico-chemical parameters of the substrates

The initial physico-chemical parameters of the different substrates before use are summarized in the Table 1. The pH values of the organic substrates ranged between 5.88 (poultry) and 8.52 (cow). The moisture content of the organic substrate before use varied between 3.43 % and 12.66 %. The ash varied between 31.48 % and 84.4 % (Table 1). The carbons of different organic substrates are in the range of 9.05 % in vegetable compost to 37.34 % in rabbit dung. The nitrogen ranged from 1.07 % in vegetable compost to 2.56 % in sheep dung. The C:N ratio of different organic substrates are in the range of 8.46 in vegetable compost to 19.39 in pig dung. Phosphorus

content ranged from 0.06 % in vegetable compost to 1.04 % in rabbit waste.

Survival, growth performance, and organic substrate utilization by earthworm

Earthworms survival rate

During the study, no mortality was observed in cow, pig and rabbit dung. But in poultry, sheep dung and vegetable compost, the mortalities were observed. In vegetable compost the mortality was observed in the whole study period.

Growth performance and organic substrate utilization by earthworm

The different parameters of growth performance and organic substrate utilization by earthworm are given in Table 2.

The growth rate varied according to different organic waste ($P < 0.05$). These values ranged between -0.06 ± 0.02 (vegetable compost) and 1.34 ± 0.11 (cow dung).

In the first week, the growth was slow, the growth rate steadily increased thereafter and it reached its maximum during the 90th day, excepted vegetable compost where the growth has decreased (Fig. 1).

Table 1 Initial physico-chemical parameters of the organic substrates

Organic substrates	pH	Moisture content %	Ash %	Organic matter %	Phosphorus (P) %	Carbon (C) %	Nitrogen (N) %	Ratio C:N
Rabbit	8.16	12.66	35.62	64.38	1.04	37.34	2.46	15.18
sheep	8.32	11.76	39.55	60.45	0.59	35.06	2.99	11.73
cow	8.52	8.71	60.24	39.76	0.37	23.06	2.06	11.19
Pig	7.94	10.29	31.48	68.52	0.42	39.74	2.05	19.39
Poultry	5.88	6.84	63.27	36.73	0.6	21.31	1.82	11.71
Vegetable compost	6.84	3.43	84.4	15.6	0.06	9.05	1.07	8.46

Fig. 1 Growth curves for earthworms (*Eisenia fetida*) in various organic substrates over a period of study (90 days)

The growth rate for *E. fetida* per gram, per worm and per day (g/worm/day) is: cow dung (1.34 ± 0.11) > pig dung (1.17 ± 0.09) > rabbit dung (0.67 ± 0.16) > poultry dung (0.38 ± 0.07) > sheep dung (0.05 ± 0.05) > vegetable compost (-1.89 ± 0.77) (Fig. 2).

Fig. 2 Growth rate of *Eisenia fetida* on different organic substrates

Fig. 3 Produce of *Eisenia fetida* on different organic substrates

The produce (worm g/kg substrate) was higher in cow dung (40.33 ± 3.23) and negative in compost vegetable (-1.89 ± 0.77) (Fig. 3).

Discussion

Physico-chemical parameters of the substrates

The pH values of the organic substrates are alkaline for rabbit, sheep, cow and pig, ranging between 7.94 and 8.52. But the pH values of poultry (5.88) and plant compost (6.84) are acids. This acidity can be proved by the large in nitrogen and mineral in poultry manure (Sherman 2003). The ash varied between 31.48 % (pig) and 84.4 % (vegetable compost). These values are relatively high because the organic substrates used contained sand, particularly the vegetable compost with 84.4 %. The carbon in cow dung is higher compared to the carbon in cow dung used by Bisht

et al. (2007) to evaluate the reproductive potential of the earthworms (*Metaphire posthuma*). The nitrogen ranged from 1.07 % in vegetable compost to 2.56 % in sheep dung. The C:N ratio of different organic substrates are in the range of 8.46 in vegetable compost to 19.39 in pig dung. The C:N ratio in cow dung is low compared to C:N ratio in cow dung used by Garg et al. (2005) to produce earthworms.

Survival, growth performance, and organic substrate utilization by earthworm

During the study, no mortality was observed in cow pig and rabbit dung. But in poultry, sheep dung and vegetable compost, mortalities were observed. The mortality in poultry dung was observed only in the first month of the study. The mortality in poultry might be due to the higher nitrogen and mineral content (Sherman 2003). It can be proved by the anaerobic conditions which developed (Garg et al. 2005). In vegetable compost the mortality is observed in the whole study period. The mortality observed in vegetable compost is due to high sand (ash: 84.4 %) contained in the vegetable compost.

Production depends on the biochemical quality of the feeds. Feeds which provide earthworms with sufficient amount of easily metabolizable organic matter and non-assimilated carbohydrates, favor growth and reproduction of earthworms (Edwards 1988). The growth rate varied according to different organic waste ($P < 0.05$). These values ranged between -0.06 ± 0.02 (vegetable compost) and 1.34 ± 0.11 (cow dung). This variation can be proved by the palatability, the type and the quality of different substrates (Tripathi and Bhardwaj 2004; Gajalakshmi et al. 2005).

In the first week, the growth was slow, the growth rate steadily increased thereafter and it reached its maximum during the 90th day, except in vegetable compost where the growth has decreased. The growth rate for *E. fetida* per gram, per worm and per day (g/worm/day) is: cow dung (1.34 ± 0.11) > pig dung (1.17 ± 0.09) > rabbit dung (0.67 ± 0.16) > poultry dung (0.38 ± 0.07) > sheep dung (0.05 ± 0.05) > vegetable compost (-1.89 ± 0.77). Several results have proved the use of cow dung in vermicomposting. Our results corroborate according to the use of cow dung in vermicomposting with the findings of Bhat et al. 2015 where the cow dung is mixed with the bagasse. But our results are different from that observed by Garg et al. (2005), where the sheep dung results are the highest compared to the cow dung. This difference is due to the biomass gain by *E. fetida* which are dependent on population density and food type (Neuhauser et al. 1980). In this study, earthworm biomass increased in all animal waste. Our results corroborate with the findings of Rathinamala et al. (2008) who reported increase in body weight of

Eisenia fetida and *Eudrilus eugeniae* feeding on different organic waste. This increase in organic waste can be proved also by presence of fungi during vermicomposting. Indeed, Pramanik and Chung (2011) have reported that the fungi in vermicomposting become additional food to the worms which contribute to the higher weight of the worms.

The produce (worm g/kg substrate) was higher in cow dung (40.33 ± 3.23) and negative in compost vegetable (-1.89 ± 0.77). The negative produce obtained is due to the high mortality observed in this substrate. However, in another experiment, the produce was 34.0 ± 1.90 mg/g by *E. fetida* species in cow dung at 27 °C. In horse waste, produce by *P. excavatus* species was about two times higher than *E. fetida*. This difference could be due to the difference in species morphology and initial characteristics of the feed waste (Edwards et al. 1998).

Conclusion

The current study proved that animal wastes (cow, sheep, pig, rabbit and poultry) and vegetable compost can be used to produce the earthworm. But the growth and produce depend on the biochemical quality of the substrates and the availability and facility for using a nutritive element. The first substrate favored by *Eisenia fetida* among the animal wastes in this study is the cow dung followed by pig dung.
